

CS 581 – ADVANCED ARTIFICIAL INTELLIGENCE

TOPIC: SEARCH

Mustafa Bilgic

<http://www.cs.iit.edu/~mbilgic>

MOTIVATION

- AI is powered by search
- Need to consider multiple possibilities and find the “optimal” one
- Just a few examples
 - Travel from one location to another
 - Find the “optimal” route
 - Game playing
 - Find the “optimal” move
 - Machine learning
 - Find the “optimal” set of parameters
 - Machine translation
 - Find the “optimal” sequence of words
 - Constraint satisfaction
 - Find the “optimal” assignment
 - ...

WE WILL STUDY

- Hill climbing, A*, genetic algorithms, simulated annealing, ...
- Maximum likelihood estimation, Bayesian estimation, expectation maximization, gradient optimization, Lagrange multipliers, policy search, ...
- Minimax, Alpha-beta search, Monte-Carlo tree search, ...

ABSTRACT REPRESENTATION

Given

- An initial state
- Available actions at each state
- A transition model
- Costs
 - A goal state and the cost of each action, OR
 - “Goodness” of each state

Find

- A sequence of actions that take you from the initial state to the goal state, where the total cost of the sequence is minimized, OR
- A maximum state

ROUTE FINDING

- The world representation
 - In(City)
- Initial state
 - In(Madison, WI)
- Goal state
 - In(Detroit, MI)
- Actions
 - Travel to the neighboring city
- Transition model
 - If you are in city A and travel to city B, the state changes from In(A) to In(B)
- Cost
 - Distance traveled

TRAVELING SALESMAN PROBLEM

- Given
 - A list of N cities
 - Distances between each pair of cities
- Find
 - A minimum-cost travel plan where the agent visits each city exactly once and returns to the city of origin

8 PUZZLE

7	2	4
5		6
8	3	1

Start State

	1	2
3	4	5
6	7	8

Goal State

8 QUEENS

GAME PLAYING

- Single-player games
 - E.g., sudoku
- Two-player games
 - E.g., tic-tac-toe, chess, Go
- Multi-player games
 - E.g., many video games
- Team games
 - E.g., robotic soccer

OUTLINE

- Route finding
 - A sequence of actions to reach from an initial state to a goal state
 - Best-first search: heuristic search, uniform cost search, A*
 - Chapter 3
- Local search
 - Start at an initial state; reach/find a maximum utility state
 - Hill climbing, simulated annealing, genetic algorithms
 - Chapter 4
- Games
 - Two-player games
 - Minimax, alpha-beta pruning, Monte-Carlo tree search
 - Chapter 5

ROUTE FINDING

CHAPTER 3

EXERCISE

- You are at an initial city D
- You are trying to reach to the city M
- The cities are not fully connected; you can travel from one city to only its neighbor cities
- You don't have access to the full map; you know only the parts you explored or discovered
- Each time you pick a city and ask where you can go from there
- You want to find the shortest path from D to M , and you want to do it as fast as possible
- Notation:
 - $c(n, n')$: the cost of traveling from n to n'
 - $h(n)$: the estimate of the distance from n to the goal
- Three settings:
 - Setting 1: You are given the c function but not h
 - Setting 2: You are given the h function but not c
 - Setting 3: You are given both c and h functions

BEST-FIRST SEARCH PSEUDOCODE

- Given
 - The initial state, goal state, available actions, action costs, and maybe a heuristic function
 - frontier – a priority queue; explored: a set
- Initialize frontier with the initial state
- While frontier is not empty
 - Pop the top node n in the frontier
 - Add n to explored
 - If n is the goal state, return the solution
 - For each child n' of n :
 - If n' is not in explored
 - If n' is not in frontier
 - Add it to frontier
 - Else if the new path to n' is better than the old path, replace the old n' with the new n' in the frontier
- Return failure // frontier is empty; goal was not found

BEST-FIRST SEARCH ALGORITHMS

- Define $f(n) = h(n) + g(n)$
 - $h(n)$: Cost estimate from n to the goal
 - $g(n)$: Cost from the initial state to n
- 1. Uniform-cost search
 - `frontier` is sorted using $g(n)$
- 2. Greedy heuristic search
 - `frontier` is sorted using $h(n)$
- 3. A* search
 - `frontier` is sorted using $f(n)$

BEST-FIRST SEARCH ALGORITHMS

- Define $f(n) = h(n) + g(n)$

- $h(n)$: Cost estimate from n to the goal
- $g(n)$: Cost from the initial state to n

1. Uniform-cost search

- frontier is sorted using $g(n)$

2. Greedy heuristic search

- frontier is sorted using $h(n)$

3. A* search

- frontier is sorted using $f(n)$

← optimal ; not informed
← informed ; not optimal
informed & optimal
if h is consistent

ROUTE FINDING EXAMPLE

- See OneNote

OPTIMAL

- Assume the optimal path cost is p^*
- Uniform cost search is guaranteed to return the optimal path
 - Expands all nodes where $g(n) \leq p^*$
- Greedy heuristic search is not optimal; ignores path costs
- A* is optimal only if h is admissible and consistent
 - Expands all nodes where $g(n) + h(n) \leq p^*$

ADMISSIBLE? CONSISTENT?

○ **Admissible** if

- $h(n)$ never overestimates the optimal cost
- That is $h(n)$ is always optimistic
- E.g., straight line distance between two cities

○ **Consistent** if

- If $h(n) \leq c(n, n') + h(n')$
 - n' is the successor of n
 - Triangle inequality
- If a heuristic is consistent, it is also admissible
(the other way around is not guaranteed)

ADMISSIBLE? CONSISTENT?

○ **Admissible** if

- $h(n)$ never overestimates the optimal cost
- That is $h(n)$ is always optimistic
- E.g., straight line distance between two cities

○ **Consistent** if

- If $h(n) \leq c(n, n') + h(n')$
 - n' is the successor of n
 - Triangle inequality
- If a heuristic is consistent, it is also admissible (the other way around is not guaranteed)

$$\underline{h(n)} \leq \underline{c(n, n')} + \underline{h(n')}$$

A* OPTIMALITY – PROOF SKETCH

1. If $h(n)$ is consistent, then $f(n)$ along any path is non-decreasing
2. When n is expanded, the optimal path to it has been found

UCS vs A*

- $A^* = \text{UCS}$ if $h(n) = 0$ for all n
- UCS searches in circles whereas A^* searches in ellipses

HEURISTICS

- How to design $h(n)$?
 - The answer is “depends on the domain” but some general principles exist
 - For example, relax the problem constraints a bit
- For travel problems
 - Flight distance
- For 8-Puzzle
 - Number of misplaced tiles
 - Manhattan distance

Goal State

COMPARING HEURISTICS

- h_i **dominates** h_j iff
 - $h_i(n) \geq h_j(n) \forall n$
- For the 8-Puzzles problem
 - Manhattan distance dominates # of misplaced tiles
- If you have multiple admissible heuristics where none dominates the other
 - Let $h(n) = \max(h_1(n), h_2(n), \dots, h_m(n))$
 - $h(n)$ is admissible and it dominates all $h_i(n)$
 - Of course, computing a heuristic is not free, and hence we need to consider the computational cost of $h(n)$ compared to each $h_i(n)$

EFFECTIVE BRANCHING FACTOR

- If the total number of nodes generated is N and the solution depth is d , then
 - b^* is the branching factor that a uniform tree of depth d would need to have in order to contain $N+1$ nodes
- $N+1 = 1 + b^* + (b^*)^2 + \dots + (b^*)^d$
- If A^* finds a solution at depth 4 using 40 nodes, what is b^* ?
 - ≈ 2.182
- A good heuristic function achieves $b^* \approx 1$

OTHER SEARCH ALGORITHMS

- Depth-first search
- Breadth-first search
- Iterative deepening search
- Bidirectional search

COMPARING ALGORITHMS

- Time complexity
- Space complexity
- Completeness
 - If there is a solution, can it find it?
- Optimality
 - Is the found solution the optimal one?

EMPIRICAL COMPARISONS

FIND THE MAXIMUM UTILITY STATE

CHAPTER 4

DISCRETE STATE SPACE SEARCH

- Each state
 - Is discrete
 - Represents a complete representation of a possible solution
 - Has a “desirability” score
 - Might have neighbors reachable through actions/moves
- The goal is to find the maximum/minimum scoring state
- Some examples
 - Bayesian network structure search
 - A state is a candidate structure; the score is BIC; actions are to “add/remove/reverse” an edge
 - 8-Queens
 - A state is placement of 8 queens on the board; the score is the number of pairs of queens attacking each other; the actions are to move a queen to another empty square
 - Traveling salesman
 - A state is a travel plan; the score is the cost of the plan; the actions are to swap the order of two neighboring cities
- The actions and state representations are not written on stone; you can define them in a different way
 - How you define the states and actions can have a profound impact on the shape of the search space

THE SEARCH LANDSCAPE

Figure 4.1 A one-dimensional state-space landscape in which elevation corresponds to the objective function. The aim is to find the global maximum.

Figure from <http://aima.cs.berkeley.edu/figures.pdf>

HILL CLIMBING

```
function HILL-CLIMBING(problem) returns a state that is a local maximum
  current  $\leftarrow$  problem.INITIAL
  while true do
    neighbor  $\leftarrow$  a highest-valued successor state of current
    if VALUE(neighbor)  $\leq$  VALUE(current) then return current
    current  $\leftarrow$  neighbor
```

Figure 4.2 The hill-climbing search algorithm, which is the most basic local search technique. At each step the current node is replaced by the best neighbor.

Figure from <http://aima.cs.berkeley.edu/algorithms.pdf>

Maximize
current \leftarrow initial

while True:

get all next states from current state
max-s \leftarrow find the maximum

if current < max-s
current \leftarrow max-s

else
return current

8-QUEENS EXAMPLE

14	12	18	13	15	12	14	14
15	14	14	13	16	13	16	16
14	17	15	14	16	16	16	16
17	16	18	15	14	15	16	16
18	14	15	15	14	16	16	16
14	14	13	17	14	12	18	18

(b)

Figure 4.3 (a) The 8-queens problem: place 8 queens on a chess board so that no queen attacks another. (A queen attacks any piece in the same row, column, or diagonal.) This position is almost a solution, except for the two queens in the fourth and seventh columns that attack each other along the diagonal. (b) An 8-queens state with heuristic cost estimate $h = 17$. The board shows the value of h for each possible successor obtained by moving a queen within its column. There are 8 moves that are tied for best, with $h = 12$. The hill-climbing algorithm will pick one of these.

Figure from <http://aima.cs.berkeley.edu/figures.pdf>

SIMULATED ANNEALING

- Optimization by Simulated Annealing
 - S. Kirkpatrick, C. D. Gelatt Jr., M. P. Vecchi
 - *Science* 13 May 1983:
 - Vol. 220, Issue 4598, pp. 671-680
 - <https://science.sciencemag.org/content/220/4598/671>

SIMULATED ANNEALING

function SIMULATED-ANNEALING(*problem*, *schedule*) **returns** a solution state

current \leftarrow *problem*.INITIAL

for *i* = 1 to ∞ **do**

T \leftarrow *schedule*(*i*)

if *T* = 0 **then return** *current*

next \leftarrow a randomly selected successor of *current*

$\Delta E \leftarrow$ VALUE(~~*current*~~) - VALUE(~~*next*~~)

if $\Delta E > 0$ **then** *current* \leftarrow *next*

else *current* \leftarrow *next* only with probability $e^{+\Delta E/T}$

max

current: 15
next: 10
diff: -5
 $e^{-5/T}$

Figure 4.4 The simulated annealing algorithm, a version of stochastic hill climbing where some downhill moves are allowed. The *schedule* input determines the value of the “temperature” *T* as a function of time.

Figure from <http://aima.cs.berkeley.edu/algorithms.pdf>

Sim. annealing. maximize
 $T \leftarrow \text{next}(T)$
current \leftarrow initial

for i in range(max_iter):

next \leftarrow a random neighbor of current

if next > current
current \leftarrow next

else
diff = next - current # negative diff/T
current \leftarrow next with prob $e^{\text{diff}/T}$

T start large & decrease it

$T \leftarrow \text{Schedule}(i)$

linear schedule (δ)

$$T = T_{in} - i \cdot \delta$$

exp schedule (T_{in}, λ, i)

$$T_{in} \cdot e^{-\lambda \cdot i}$$

SIMULATED ANNEALING EXAMPLE

GIF from https://en.wikipedia.org/wiki/Simulated_annealing

EVOLUTIONARY ALGORITHMS

- A population of states
 - Each state has a “fitness” score
 - Select candidate states from the population
 - “Recombine” them to create an “offspring”
 - Optionally, mutate the “offspring”
-
- Reading: <https://doi.org/10.1007/s11042-020-10139-6>

EVOLUTIONARY ALGORITHMS – GENETIC ALGORITHM

```
function GENETIC-ALGORITHM(population, fitness) returns an individual
  repeat
    weights  $\leftarrow$  WEIGHTED-BY(population, fitness)
    population2  $\leftarrow$  empty list
    for  $i = 1$  to SIZE(population) do
      parent1, parent2  $\leftarrow$  WEIGHTED-RANDOM-CHOICES(population, weights, 2)
      child  $\leftarrow$  REPRODUCE(parent1, parent2)
      if (small random probability) then child  $\leftarrow$  MUTATE(child)
      add child to population2
    population  $\leftarrow$  population2
  until some individual is fit enough, or enough time has elapsed
  return the best individual in population, according to fitness

function REPRODUCE(parent1, parent2) returns an individual
   $n \leftarrow$  LENGTH(parent1)
   $c \leftarrow$  random number from 1 to  $n$ 
  return APPEND(SUBSTRING(parent1, 1,  $c$ ), SUBSTRING(parent2,  $c + 1$ ,  $n$ ))
```

Figure 4.7 A genetic algorithm. Within the function, *population* is an ordered list of individuals, *weights* is a list of corresponding fitness values for each individual, and *fitness* is a function to compute these values.

8-QUEENS EXAMPLE

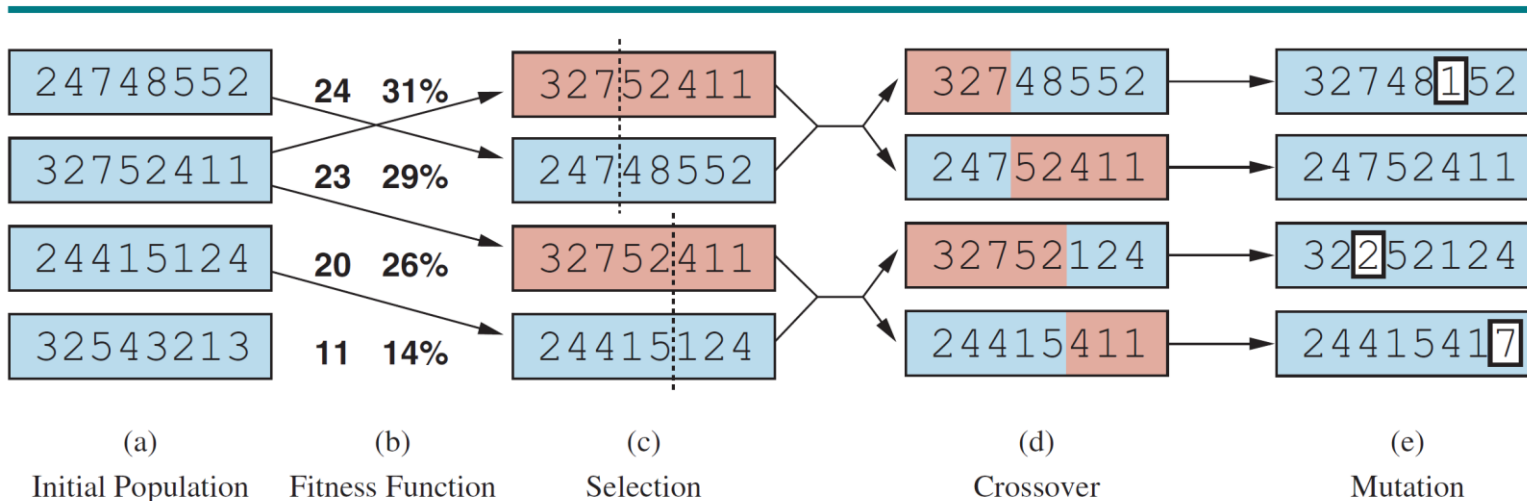

Figure 4.5 A genetic algorithm, illustrated for digit strings representing 8-queens states. The initial population in (a) is ranked by a fitness function in (b) resulting in pairs for mating in (c). They produce offspring in (d), which are subject to mutation in (e).

Figure from <http://aima.cs.berkeley.edu/figures.pdf>

8-QUEENS EXAMPLE

Figure 4.6 The 8-queens states corresponding to the first two parents in Figure ??(c) and the first offspring in Figure ??(d). The green columns are lost in the crossover step and the red columns are retained. (To interpret the numbers in Figure ??: row 1 is the bottom row, and 8 is the top row.)

Figure from <http://aima.cs.berkeley.edu/figures.pdf>

GAME PLAYING

CHAPTER 5

GAMES

- A **multiagent** and **competitive** environment
- Agents try to maximize their own utilities at the expense of other agents' utilities
- Constant-sum games, where the sum of the utilities in the end is constant
 - E.g., win = +1, loss = -1, tie = 0
 - E.g., win = +1, loss = 0, draw = 0.5

SEARCH FOR THE BEST MOVE IS EXPENSIVE

○ Chess

- Average branching factor: ~ 35
- If a game lasts 40 moves per player
 - Search tree depth is 80
 - Number of nodes: $35^{80} \approx 10^{123}$
 - Number of estimated atoms in the universe: 10^{80}
- You still must make a decision before you can calculate the optimal move

○ [https://en.wikipedia.org/wiki/Game_complexity#Complexities of some well-known games](https://en.wikipedia.org/wiki/Game_complexity#Complexities_of_some_well-known_games)

SEARCH FOR THE BEST MOVE IS EXPENSIVE

○ Chess

- Average branching factor: ~ 35
- If a game lasts 40 moves per player
 - Search tree depth is 80
 - Number of nodes: $35^{80} \approx 10^{123}$
 - Number of estimated atoms in the universe: 10^{80}
- You still must make a decision before you can calculate the optimal move

80 by 35

○ [https://en.wikipedia.org/wiki/Game_complexity#Complexities of some well-known games](https://en.wikipedia.org/wiki/Game_complexity#Complexities_of_some_well-known_games)

TWO-PLAYER GAME TREE

- Two players: MAX and MIN
- MAX moves first
- Both are maximizing their own utility
- In a constant-sum game search tree
 - MAX chooses a “max” move
 - MIN chooses a “min” move

TIC-TAC-TOE

Figure 5.1 A (partial) game tree for the game of tic-tac-toe. The top node is the initial state, and MAX moves first, placing an X in an empty square. We show part of the tree, giving alternating moves by MIN (O) and MAX (X), until we eventually reach terminal states, which can be assigned utilities according to the rules of the game.

Figure from <http://aima.cs.berkeley.edu/figures.pdf>

OPTIMAL STRATEGY

- An optimal strategy leads to outcomes at least as good as any other strategy when one is playing on *infallible* opponent
- What if the opponent is not playing optimally?

MINIMAX EXAMPLE

Figure 5.2 A two-ply game tree. The \triangle nodes are “MAX nodes,” in which it is MAX’s turn to move, and the ∇ nodes are “MIN nodes.” The terminal nodes show the utility values for MAX; the other nodes are labeled with their minimax values. MAX’s best move at the root is a_1 , because it leads to the state with the highest minimax value, and MIN’s best reply is b_1 , because it leads to the state with the lowest minimax value.

ALPHA-BETA PRUNING

- Keep lower and upper bounds (α , β)
- MAX updates the lower bound α
- MIN updates the upper bound β
- Both pass the current bounds to their children
- $\text{MIN}(\alpha, \beta)$ prunes if $v \leq \alpha$; MAX already has a better choice α
- $\text{MAX}(\alpha, \beta)$ prunes if $v \geq \beta$; MIN already has a better choice β

EXAMPLE: MIN PRUNES

EXAMPLE: MAX PRUNES

MINIMAX EXAMPLE

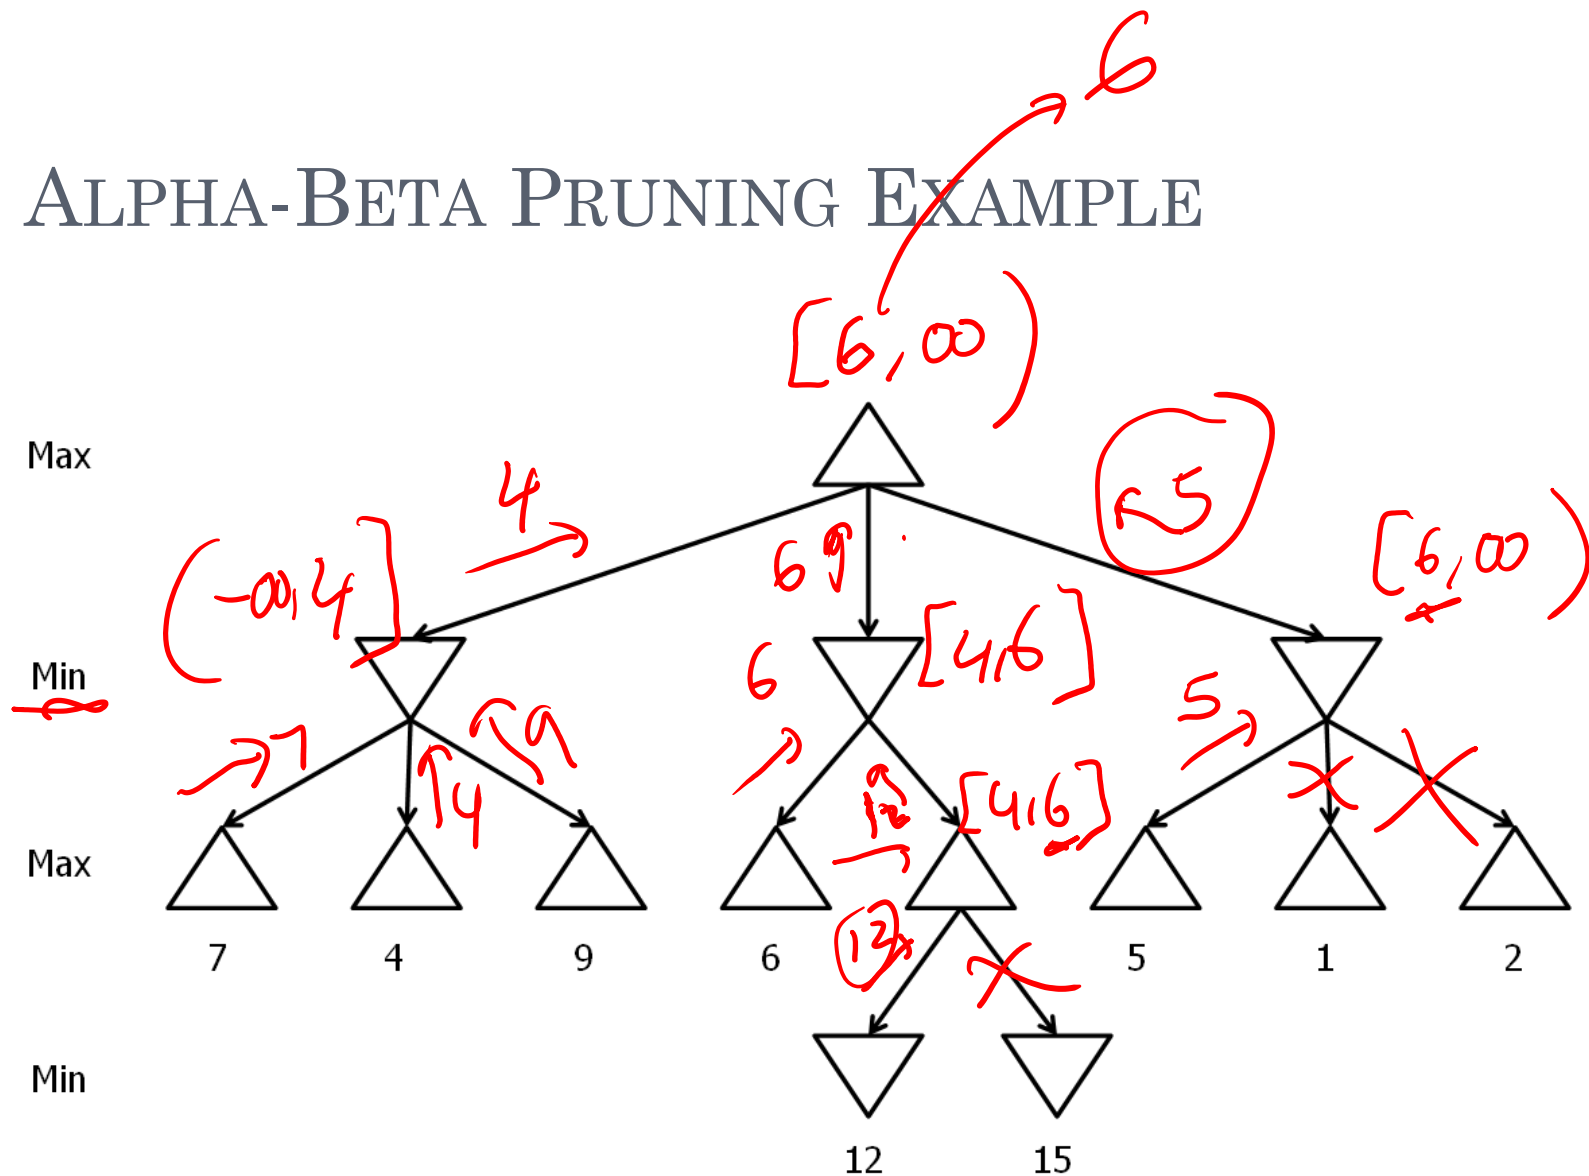

MINIMAX EXAMPLE

ALPHA-BETA PRUNING EXAMPLE

ALPHA-BETA PRUNING EXAMPLE

Monte-Carlo Tree Search

```
function MONTE-CARLO-TREE-SEARCH(state) returns an action
  tree  $\leftarrow$  NODE(state)
  while IS-TIME-REMAINING() do
    leaf  $\leftarrow$  SELECT(tree)
    child  $\leftarrow$  EXPAND(leaf)
    result  $\leftarrow$  SIMULATE(child)
    BACK-PROPAGATE(result, child)
  return the move in ACTIONS(state) whose node has highest number of playouts
```

Figure 5.11 The Monte Carlo tree search algorithm. A game tree, *tree*, is initialized, and then we repeat a cycle of SELECT / EXPAND / SIMULATE / BACK-PROPAGATE until we run out of time, and return the move that led to the node with the highest number of playouts.

MONTÉ-CARLO TREE SEARCH

Figure 5.10 One iteration of the process of choosing a move with Monte Carlo tree search (MCTS) using the upper confidence bounds applied to trees (UCT) selection metric, shown after 100 iterations have already been done. In (a) we select moves, all the way down the tree, ending at the leaf node marked 27/35 (for 27 wins for black out of 35 playouts). In (b) we expand the selected node and do a simulation (playout), which ends in a win for black. In (c), the results of the simulation are back-propagated up the tree.

EXPLORATION VS EXPLOITATION TRADE-OFF

- Exploit current winning moves; explore to find better ones
- UCT – Upper confidence bound for trees
- $UCT = \frac{w_i}{n_i} + C \times \sqrt{\frac{\log N_i}{n_i}}$
- w_i : # of wins
- n_i : # of plays
- N_i : # of plays at its parent
- C : exploration parameter

EXPLORATION VS EXPLOITATION TRADE-OFF

- Exploit current winning moves; explore to find better ones

- UCT – Upper confidence bound for trees

exploit

$$UCT = \frac{w_i}{n_i} + C \times \sqrt{\frac{\log N_i}{n_i}}$$

exploration

- w_i : # of wins

- n_i : # of plays

- N_i : # of plays at its parent

- C : exploration parameter

$$C = \sqrt{2}$$

$$C = 1.4$$

EARLY CUT-OFF

- To be able to calculate utilities, the search algorithms must reach the terminal states
 - Of course, this is not practical for most games
- A solution: early cut-off with approximate evaluation functions

HEURISTIC EVALUATION FUNCTIONS

- An estimate of the utility is returned rather than the actual utility
- For e.g., define features and a weighted feature combination function
 - e.g., $\text{EVAL}(s) = w_1f_1(s) + w_2f_2(s) + \dots + w_nf_n(s)$
 - E.g., chess: pawn: 1, knight or bishop: 3, rook: 5, queen: 9
- Use machine learning to learn and predict the utilities of the states
- Note that the utility of the state depends on whose turn it is

THE BEGINNING / OPENING

- Typically, the utility of a state can be approximated more accurately the closer it is to the end of the game
- The beginning of the game is the furthest away from the end
- A strategy:
 - Use an “opening” book
 - For e.g., see <https://lichess.org/analysis#explorer> for the most common moves
